Description

Method for determining the amplitude and phase angle of
a measuring signal corresponding to a current or
5 voltage of an electrical power supply network

The invention relates to a method for determining the
amplitude and phase angle of a measuring signal
corresponding to a current or a voltage on an
10 electrical power supply network by using sampled values
of the measuring signal, a model of the measuring
signal containing at least a sinusoidal component being
used to calculate the model amplitude and phase
parameters of the measuring signal with the sampled
15 values by applying a recursive least-squares estimation
method.

A method of this type is described in an article by
M.S. Sachdev and M. Nagpal "A recursive least squares
20 error algorithm for power system relaying and
measurement applications", IEEE Trans. on Power
Delivery, Vol. 6, No. 3, July 1991. In the case of this
known method, sampled values are formed from a
measuring signal corresponding to a current or voltage
25 of an electrical power supply network and, by means of
a linear least-squares estimation method, by using a
sinusoidal signal model that models the measuring
signal, are used to form a complex vector, which
specifies the amplitude and phase angle of the
30 measuring signal. In this case, in a first step the
~~real and imaginary part of the vector are in each case~~
determined on their own. Then, in a second step, by
means of a coordinate transformation, the polar
coordinate representation of the complex vector, that
35 is to say the magnitude and phase of the vector, can be
determined from the real and imaginary part of the
vector.

In the case of the known method, it is assumed that the frequency of the measuring signal is known. If this is not so, or if the frequency changes, then a separate method is needed in order to determine the frequency of the measuring signal. Methods are known there, for example, which measure the distance of the zero transitions of the measuring signal and, on the basis of measuring this period, determine the frequency of the measuring signal, see, for example, E. Schröder (Editor): "Lexikon Meß- und Automatisierungstechnik" [Measurement and Automation Encyclopedia], VDI-Verlag, 1992, p.204. Also known is a method for frequency measurement in which the measured signal to be examined is in each case filtered in parallel by a high-pass filter and an all-pass filter (German patent DE 42 11 946). The frequency of the measuring signal can be determined via the ratio between the amplitudes of the output signals from these two filters.

The invention is based on the object of specifying a method with which all the significant variables of the measuring signal can be determined simultaneously and quickly.

In the case of a method of the type indicated at the beginning, this object is achieved, according to the invention, in that use is made of a model of the measuring signal containing the sinusoidal component in accordance with the relationship $y = A \cdot \sin(2\pi ft + \varphi)$, y designating an instantaneous value of the model of the measuring signal, A the amplitude, f the frequency, φ the phase angle and t the time; by using this model of the measuring signal and by using the sampled values, by means of a recursive nonlinear least-squares estimation method, the model frequency parameter of the measuring signal is also determined by the estimation together with the model amplitude parameter and the model phase angle parameter.

Although it is known, from the book by H.-J. Hermann, "Digitale Schutztechnik" [Digital Protection Engineering], 1997, pp. 110-111, to use a recursive, nonlinear least-squares estimation method in protection engineering, the book does not contain any reference to the fact that by using such an estimation method, sampled values of a measuring signal can be used to determine the amplitude, phase angle and frequency of the measuring signal in a single measured-value processing process.

A significant advantage of the method according to the invention is, however, precisely that the sampled values of the measuring signal are used to determine the frequency, as well as the amplitude and phase angle, in a measured-value processing process, and therefore the amplitude, phase angle and frequency of the measuring signal are associated with the same point in time.

Furthermore, the patent DE 42 05 300 C1 discloses a method with which the phase angle and the amplitude of a periodic signal can be determined via a phase-locked control loop (PLL (Phase-Locked Loop)).

The use of the model for the measuring signal $y = A \cdot \sin(2\pi ft + \varphi)$ leads to good results if the measuring signal has a purely sinusoidal waveform. If there is a DC component present in the measuring signal, a model of the measuring signal in accordance with the relationship $y = A \cdot \sin(2\pi ft + \varphi) + d$ is advantageously used, the summand d modeling the DC component of the measuring signal.

5

$$y = A \cdot \sin \left(2\pi \sum_{i=0}^n (f^{(i)} t^i) t + \varphi \right) + d$$

In a further advantageous refinement of the method according to the invention, the values of the amplitude A, the phase angle ϕ and the frequency f determined by the estimation method are output as results only when the estimation error is less than a smallest permitted estimation error. This has the advantage that, in particular, the values estimated at the start of the method and afflicted by large estimation errors are not output, and therefore the large

estimation errors cannot have any negative consequences for a user of the method.

In order to explain the invention further,

5 figure 1 shows, by using a block diagram, the progress of an exemplary embodiment of the method according to the invention,

figure 2 shows waveforms of a measuring signal, of an estimated signal y_s determined for the measuring signal by using a model $y = A \cdot \sin(2\pi ft + \varphi)$ and of the resulting error F ,

figure 3 shows results of the method according to the invention in the case of a purely sinusoidal measuring signal when use is made of an appropriate model of the measuring signal, separated in accordance with the time-based waveforms of amplitude, phase angle and frequency,

figure 4 shows results of the method according to the invention in the case of a measuring signal subject to an offset, that is to say containing a DC component, separated in accordance with the time-based waveforms of amplitude, phase angle and frequency, when use is made of a model of the measuring signal that does not model any DC component, and

figure 5 shows results of the method according to the invention in the case of a measuring signal subject to an offset, that is to say containing a DC component, separated in accordance with the time-based waveforms of amplitude, phase angle, frequency and DC component, when use is made of a model of the measuring signal that models a DC component.

According to figure 1, after being sampled in a sample-and-hold circuit 1 and after analog-digital conversion in an analog-digital converter 2, sampled values y_m of a measuring signal u_m are present on an input 3 of a data processing system 4. The data processing system 4

contains a unit 5 for carrying out a recursive nonlinear least-squares estimation method.

At the beginning of the recursive estimation method,
5 starting values SW for the variables amplitude A, frequency f and phase angle ϕ are input into the unit 5 and are present on the output 6 of the unit 5 as estimation output values $\underline{\Theta}_{(0)}$. The estimation output values $\underline{\Theta}_{(0)}$ are led to a block 7, which contains a model
10 of the measuring signal.

In the block 7, the estimation output values $\underline{\Theta}_{(0)}$ are used, taking into account the model of the measuring signal, to determine a starting signal value y_{s0} , which
15 is output at the output of the block 7 and led to an input 8 of the unit 5.

The unit 5 uses a (first) sampled value y_m of the measuring signal u_m and the starting signal value y_{s0} to
20 determine an estimation error F_{estim} in accordance with the relationship (3) recited below. This estimation error will lie above a permitted smallest estimation error. Therefore, in the unit 5 and starting from the estimation output values $\underline{\Theta}_{(0)}$, in accordance with the
25 rules for recursive nonlinear least-square estimations, new estimated values $\underline{\Theta}_{(1)}$ are formed in accordance with the relationship (1) below, are output at the output 6 of the unit 5 and led to block 7.

30 In block 7, the new estimated values $\underline{\Theta}_{(1)}$ are used to determine an estimated signal value y_{s1} , which is output at the output of block 7 and is led to the input 8 of the unit 5. The unit 5 uses the (first two) sampled values y_m and the starting signal value y_{s0} and the
35 estimated signal value y_{s1} again to form an estimation

error F_{estim} in accordance with the relationship (3) recited below. This estimation error will generally also lie above the smallest permitted estimation error. Therefore, in the unit 5 and starting from the
 5 estimated values $\underline{\Theta}_{(1)}$ on the preceding estimation, new estimated values $\underline{\Theta}_{(2)}$ are again determined in accordance with the relationship (1). These steps are repeated until the estimation error F_{estim} lies below a smallest permitted estimation error.

10

In order to determine whether the estimation error F_{estim} lies below a smallest permitted estimation error, use is made of a block 9. Via an input 10, block 9 obtains from the unit 5 the sampled values y_m of the measuring
 15 signal u_m , the starting signal value y_{s0} and the estimated signal values y_{s1} to y_{sk} , which are buffered in the unit 5. When the estimation error F_{estim} lies below a smallest permitted estimation error, then a switching signal, which switches a switch 12 on, is
 20 output at an output 11 of the block 9. The switch 12 then forwards the estimated values $\underline{\Theta}_{(k)}$ present at the output 6 of the unit 5 to an output 13 of the data processing system 4. The estimated values $\underline{\Theta}_{(k)}$ are then output as the resulting values from the estimation
 25 method and constitute the values for amplitude, frequency and phase angle of the measuring signal, estimated with sufficient accuracy. After that, the estimation method continues to run as described above and permits continuous determination of the estimated
 30 values $\underline{\Theta}_{(k)}$.

The unit 5 determines the estimated values $\underline{\Theta}_{(k)}$ in accordance with the following relationship (1).

$$\underline{\Theta}_{(k)} = \underline{\Theta}_{(k-1)} + \underline{P}_{(k)} \underline{\gamma}_{(k)} \left(y_{(k)} - h(\underline{\varphi}_{(k)}, \underline{\Theta}_{(k-1)}) \right) \quad (1)$$

In relationship (1), $\underline{\Theta}_{(k)}$ represents a vector which contains the estimated values of the variables to be determined, that is to say, here, the amplitude A, frequency f and phase angle φ , after k estimation steps; $\underline{\Theta}_{(k-1)}$ designates a vector which results in the case of the estimation after k-1 estimation steps. The matrix $\underline{P}_{(k)}$ is a symmetrical precision matrix, as it is known, whose determination is presented further below using the relationship (2). The function $h(\underline{\varphi}_{(k)}, \underline{\Theta}_{(k-1)})$ contains the model of the measuring signal. The vector $\underline{\gamma}_{(k)}$ contains the partial derivatives of the model $h(\underline{\varphi}_{(k)}, \underline{\Theta}_{(k-1)})$ of the measuring signal with respect to the parameters of the model of the measuring signal, that is to say the derivatives with respect to amplitude, phase angle and frequency. The variable $y_{(k)}$ is the kth sampled value of the measuring signal.

In order to determine the precision matrix $\underline{P}_{(k)}$, use is made of a relationship (2).

$$\underline{P}_{(k)} = \frac{1}{\lambda} \left(\underline{P}_{(k-1)} - \frac{\underline{P}_{(k-1)} \cdot \underline{\gamma}_{(k)}}{\lambda + \underline{\gamma}_{(k)}^T \underline{P}_{(k-1)} \underline{\gamma}_{(k)}} \cdot \underline{\gamma}_{(k)}^T \underline{P}_{(k-1)} \right) \quad (2)$$

The factor λ determines the exponential weighting of preceding sampled values of the measuring signal. At the beginning of the method, a starting value is used for the precision matrix $\underline{P}_{(k)}$.

The estimation error F_{estim} after the kth estimation is determined by means of the relationship

$$F_{\text{Schätz}} = \frac{1}{N} \sum_{i=k-N+1}^k (y_{mi} - y_{si})^2 \quad (3)$$

Here, N is the number to be taken into account of the sampled values y_m of the measuring signal u_m and of the estimated signal values y_s , y_{mi} is the i th sampled value of the measuring signal u_m and y_{si} is the i th estimated signal value.

The estimation error F_{estim} is determined by N sampled values y_{mi} of the measuring signal u_m and N estimated signal values y_{si} being evaluated. An appropriate magnitude for N is the quotient of the (sampling frequency of the sample-and-hold circuit 1) / (estimated frequency), but N can also be selected to be larger. During the first estimation pass, the value used for N is the quotient of (sampling frequency of the sample-and-hold circuit 1) / (starting value SW of the frequency). When, at the beginning of the estimation method, N sampled values y_{mi} of the measuring signal u_m , or N estimated signal values y_{si} are not yet present, then only the present values are used to determine the estimation error F_{estim} .

Further details relating to carrying out recursive nonlinear least-squares estimation methods are described in the documents J. Wede; D. Werner: "Echtzeitprozeßmodelle auf der Basis von Parameterschätzverfahren" [Real-time process models based on parameter estimation methods], automation engineering series, Vol. 214, VEB Verlag Technik, Berlin, 1985, p.p. 30-34, pp. 44-50, 56, 57, and Hans-Joachim Herrmann: "Digitale Schutztechnik: Grundlagen, Software, Ausführungsbeispiele" [Digital Protection Engineering: Principles, Software, Design Examples], VDE Verlag 1997, pp. 104-113, and A. Jurisch: "Digitale Impedanzmeßverfahren auf der Basis von Identifikationsmethoden" [Digital Impedance Measuring Methods Based on Identification Methods], Dissertation, Technische Hochschule Zittau, 1990, Annex 4.6.3.

Figure 2 shows the time-based waveform of a sinusoidal measuring signal u_m , whose amplitude, frequency and phase angle

202210-EE/FE001

are to be determined by using the estimation method according to figure 1. Also shown over time, as the curve y_s , are the estimated signal values $y_{s1} \dots y_{sk}$ which are output at the output of block 7. Also shown

5 is the waveform of the values of the error F which results from the difference between the measuring signal u_m and the estimated signal values $y_{s1} \dots y_{sk}$, over time t . The waveforms shown result from an estimation method which is carried out by using the

10 model $y = A \cdot \sin(2\pi ft + \varphi)$ for the measuring signal. It can be seen that the waveform of the curve y_s is the same as the waveform of the measuring signal u_m after about 20 ms; the error F then assumes very small values. The estimation method therefore permits the

15 correct determination of the amplitude, the frequency and the phase angle of the measuring angle after about one period of the measuring signal u_m .

In figure 3, taking into account the waveforms shown in

20 figure 2, the estimated values $\Theta_{(1)} \dots \Theta_{(k)}$, linked with the estimated signal values $y_{s1} \dots y_{sk}$ are plotted against the time t , separated in accordance with the variables A , ω and $2\pi f$ and φ that determine them. In an upper graph, figure 3 shows the waveform of the

25 amplitude A determined by the estimation method according to figure 1, in a central graph the waveform of the variable $\omega = 2\pi f$ that is proportional to the frequency f , and in a lower graph the waveform of the phase angle φ , in each case plotted against time.

30 According to figure 2, the result that the time-based waveforms have reached a steady state at their final value after about 20 ms with the smallest permitted estimation error, and indicate the result of the estimation method.

35

Figure 4 shows, in a manner of representation which is the same as figure 3, the time-based waveforms

of amplitude A , frequency f and phase angle φ determined in a further estimation by using the model of the measuring signal $y = A \cdot \sin(2\pi ft + \varphi)$ if use is made of sampled values of a measuring signal which contains a DC component. The waveforms of frequency and phase angle also contain large time-based fluctuations for times greater than 20 ms. These fluctuations point to an erroneous estimation and are a reference to the fact that the selected model is not beneficial for a measuring signal containing a DC component.

Figure 5 shows the time-based waveforms of amplitude A , frequency f , phase angle φ and DC component d determined in an estimation using the model $y = A \cdot \sin(2\pi ft + \varphi) + d$ for the measuring signal, if use is made of sampled values of a measuring signal which contains a DC component. By using the model just mentioned of the measuring signal, fluctuations in the time-based waveforms of frequency and phase angle are avoided; consequently, an estimation which is better with regard to the estimation error is carried out.
